NH<sub>3</sub> synthesis

## ABSTRACT

The urgency of mitigating climate change has prompted us to seek more sustainable approach to ammonia (NH<sub>3</sub>) synthesis via dinitrogen (N<sub>2</sub>) photofixation process by using clean solar energy. Herein, a series of Mn-doped sea-urchin-like monoclinic W<sub>18</sub>O<sub>49</sub> microspheres (Mn-W<sub>18</sub>O<sub>49</sub>), which are constructed by nanorods with [010] growth orientation, are fabricated using a facile solvothermal process. It is found that the Mn<sup>2+</sup> ions can replace the W sites in the W<sub>18</sub>O<sub>49</sub> lattice and intervene the formation of microsphere-like structure, but facilitate the photoinduced charge separation and migration in Mn-W<sub>18</sub>O<sub>49</sub>, and thus cause a promoted N<sub>2</sub> photofixation ability compared with the single W<sub>18</sub>O<sub>49</sub>. Moreover, the surface Mn<sup>2+</sup> sites in the monoclinic nanorods of W<sub>18</sub>O<sub>49</sub> microspheres play multiple roles in promoting the chemisorption of N<sub>2</sub> and H<sub>2</sub>O molecules and weakening the ultra-stable N≡N bond for the NH<sub>3</sub> production through proton coupling process. Among those Mn-W<sub>18</sub>O<sub>49</sub> products fabricated, 3.0% Mn-doped W<sub>18</sub>O<sub>49</sub> product achieves the highest NH<sub>3</sub> production activity of 97.9 μmol g<sup>-1</sup> h<sup>-1</sup> under Xe-lamp's full spectrum irradiation, 2.3 times higher than that of the single W<sub>18</sub>O<sub>49</sub>. The present sea-urchin-like Mn-W<sub>18</sub>O<sub>49</sub> exhibits both excellent durability and efficient N<sub>2</sub> photofixation ability, which are of significance in sunlight utilization for artificial N<sub>2</sub> fixation and renewable energy conversion.

## 1. Introduction

Ammonia (NH<sub>3</sub>) synthesis has been thought as the cornerstone of modern agriculture and chemical industry for the past centuries, and the Haber-Bosch process is the most economical route for NH<sub>3</sub> synthesis through dinitrogen (N<sub>2</sub>) fixation in the world [1,2]. However, almost 2% of the world's annual energy supply was used in this single reaction only for maintaining the necessary high temperature (~300 °C) and high pressure (over 100 atm) condition, and the major resource of H<sub>2</sub> in the N<sub>2</sub> fixation process originates from industrial steam-reforming of natural gas, which would also generate large quantities of CO<sub>2</sub> [3]. Therefore, it is significantly meaningful to explore an artificial N<sub>2</sub> fixation reaction only use water as H resource under mild condition. In 1977, Schrauzer and Guth firstly reported that TiO<sub>2</sub>-based materials have an ability to reduce N<sub>2</sub> into NH<sub>3</sub> under UV light irradiation [4]. After that, lots of semiconducting materials such as metal oxides/sulfides [5–7], bismuth oxyhalides [8–10], and carbonaceous matters [11] have been explored in this area.

Over the past years, tungsten suboxides (WO<sub>3-x</sub>) have been intensively investigated because of the distinctive physical and chemical properties. Among them, W<sub>18</sub>O<sub>49</sub> is one of the most investigated ones because of its stable defect structure and promising properties [12]. In

1986, WO<sub>3-x</sub> was firstly used as photocatalysts for N<sub>2</sub> reduction, it confirmed that the WO<sub>2.96</sub> is active species and the N<sub>2</sub> was reduced to NH<sub>3</sub> through a thermal chemical reaction (but not a photochemical one) [13]. More recently, Mo-doped W<sub>18</sub>O<sub>49</sub> ultrathin nanowires were fabricated and delivered a N<sub>2</sub> photofixation ability under a mild reaction condition, and it was found that the doped Mo species act as active sites for enhancing the chemisorption of N<sub>2</sub> molecules [14]. Also, it was reported that g-C<sub>3</sub>N<sub>4</sub>/W<sub>18</sub>O<sub>49</sub> and Ag/g-C<sub>3</sub>N<sub>4</sub>/W<sub>18</sub>O<sub>49</sub> heterojunctions have full-spectrum-driven N<sub>2</sub> photofixation ability. Among which, W<sub>18</sub>O<sub>49</sub> mainly plays a role as light absorber to form more photo-generated electrons for recombining the holes in the g-C<sub>3</sub>N<sub>4</sub> through “Z-scheme” mechanism, and Ag loading can promote the electron-hole pair separation [15,16].

Since most of researches are based on the simulation of biological N<sub>2</sub> fixation of the nitrogenase [17–20], the doping elements of N<sub>2</sub> fixation materials are mainly focused on Fe and/or Mo [21–25]. Although some researchers discovered that the Mo ions doped in semiconductor could enhance the N<sub>2</sub> chemisorption and activation abilities [14,26], most of them are not efficient visible-light-driven photocatalysts, which lead to low sunlight utilization and catalytic efficiency during the N<sub>2</sub> photofixation process. Therefore, developing new doped photocatalysts with more efficient, resourceful, wide spectral response

and stable performance is full of significance for  $N_2$  photofixation reaction. From this perspective, Mn, as a more resourceful element in the earth, would be attractive doping element even though there is no investigation on Mn-doped semiconductors for photocatalytic  $N_2$  photofixation application as far as we know.

Herein, a series of Mn-doped sea-urchin-like monoclinic  $W_{18}O_{49}$  microspheres ( $Mn-W_{18}O_{49}$ ), which are constructed by nanorods with [010] growth orientation and diameter of 5–10 nm, were synthesized via a facile solvothermal process. It was found that  $Mn^{2+}$  ions can replace the W sites of monoclinic  $W_{18}O_{49}$  nanorods and intervene the formation of microsphere-like morphology of  $W_{18}O_{49}$ , but it does not change the growth orientation and shape of the nanorods in  $Mn-W_{18}O_{49}$ . Moreover, it is firstly found that  $Mn^{2+}$ -doped sites in  $W_{18}O_{49}$  can not only act as chemisorption and activation centers of  $N_2$  and  $H_2O$  molecules, but also facilitate the photoinduced charge separation and migration in  $Mn-W_{18}O_{49}$ , and thus cause an efficiently enhanced  $N_2$  photofixation ability compared to the single  $W_{18}O_{49}$  microspheres under full spectrum (UV–vis) or visible light irradiation of Xe-lamp. The effects of Mn doping on the microstructure, optical absorption, photoinduced charge separation and photocatalytic  $N_2$  fixation ability of the  $Mn-W_{18}O_{49}$  are discussed detailed.

## 2. Experimental

### 2.1. Material syntheses

Mn-doped  $W_{18}O_{49}$  microspheres were prepared via a facile solvothermal process. Typically, 1.0 mmol  $WCl_6$  was dissolved in 35 mL of ethanol, which was vigorously stirred to obtain a yellow transparent solution, then different amount of  $MnCl_2 \cdot 4H_2O$  was added into the solution. After further stirring for 5 min, the resultant solution was put into a Teflon-lined stainless autoclave (volume of 40 mL) and treated at 180 °C for 24 h. After cooled to the room temperature, the deep blue precipitate was separated and washed with deionized water and ethanol for three times, and then dried in the vacuum oven at 70 °C for 10 h to obtain Mn-doped  $W_{18}O_{49}$  microspheres.

By varying the addition amount of Mn species, Mn-doped  $W_{18}O_{49}$  microspheres containing different Mn-doping contents were produced and denoted as  $xMn-W_{18}O_{49}$  products, where  $x$  is the molar percentage of the doped Mn species. Also, the single  $W_{18}O_{49}$  was synthesized through the same reaction condition without the addition of Mn resource. The Mn and W elemental composition in those  $xMn-W_{18}O_{49}$  products are determined using ICP-AES technique. As seen in Table 1, the actual Mn-doping content is basically close to the respective addition contents during the synthesis process.

### 2.2. Materials characterization

The crystal phases of samples were analyzed based on the X-ray diffraction (XRD) patterns detected using a Bruker D8 advance X-ray diffractometer with Cu K $\alpha$  irradiation ( $\lambda = 0.154178$  nm) operated at 40 kV and 40 mA with a scan rate of  $5^\circ \text{ min}^{-1}$  in the range of  $2\theta = 20^\circ$ – $70^\circ$  and  $1^\circ \text{ min}^{-1}$  in the range of  $2\theta = 20^\circ$ – $35^\circ$  with the commercial pure  $SrTiO_3$  as reference matter. The morphologies and microstructures were characterized using Zeiss-Sigma field emission scanning electron microscope (FESEM) and JEOL LaB $_6$  JEM-2100 (HR) high-resolution transmission electron microscope (HRTEM). X-ray photoelectron

spectra (XPS) were conducted on a VG Multilab 2000 spectrometer (Thermo Elctron) with Al K $\alpha$  source. The absorption spectra were performed using diffuse reflection spectra (DRS, Shimadzu UV-3600), and photoluminescence (PL) spectra were carried out on a Hitachi Model F-6800 fluorescence spectrophotometer. The concentrations of manganese and tungsten were determined by the ICP-AES method using a Thermo Fisher IRIS Intrepid II XSP. Liquid  $N_2$  adsorption-desorption isotherms at 77 K were performed by a Micrometrics ASAP 2460 system.  $N_2$  temperature-programmed-desorption-mass spectrum ( $N_2$ -TPD-MS) were determined by using Autochem II (TPD)-Cirrus 2 (MS). The sample was firstly heated to 300 °C in flowing Ar for 3 h, and purge high pure  $N_2$  for 1 h under the room temperature, and then Ar purge the sample for 1 h to decrease the physical adsorbed  $N_2$  on the surface. Finally, the sample heated to 850 °C at a heating rate of  $10^\circ \text{ C min}^{-1}$  under Ar flowing. Electron paramagnetic resonance (EPR) spectra were collected on a MS-5000 spectrometer at room temperature.

Transient photocurrent curve was obtained by using a CHI model 618C electrochemical analyzer and a standard three-electrode system, in which platinum electrode, silver-chlorine silver electrode and sample electrode acted as the counter electrode, reference electrode and work electrode, respectively. As for the preparation of work electrode, 1.0 mg of sample was dispersed into 0.5 mL of Nafion ethanol solution (0.05 wt %) under stirring and sonication for 3 min, then the result solution was dripped on clean fluorine-doped tin oxide (FTO) glass. The film with 1.0  $\text{cm}^2$  active area was readied for photocurrent and after air-drying for at least 30 min. In general, the three electrodes were immersed into a  $Na_2SO_4$  solution (0.5 M) and well connected with the analyzer. Before irradiation, the suspension was continuously purged by  $N_2$  to remove  $O_2$ , and then illuminated by visible light ( $\lambda > 400$  nm) of 300 W Xe-lamp with an additional cutoff filter.

The measurement of flat-band potential ( $E_{fb}$ ) were almost same as the test of transient photocurrent curve, the reference electrode was still silver-chlorine silver electrode (0.5 M  $Na_2SO_4$  solution,  $E^0 = 0.198$  V vs. NHE), and the  $E_{fb}$  value was determined by the Mott-Schottky relation [27]:

$$C^{-2} = (2/e\epsilon\epsilon_0 N_d)[V_a - E_{fb} - kT/e]$$

where,  $C$  is space charge layer capacitance,  $e$  is electron charge,  $\epsilon$  is dielectric constant,  $\epsilon_0$  is permittivity of vacuum,  $N_d$  is electron donor density,  $V_a$  is the applied potential, and  $E_{fb}$  is flat band potential.

### 2.3. Photocatalytic activity measurement

The  $N_2$  photofixation activity was measured using a home-made vessel illuminated by the full spectrum of a 300 W Xe-lamp or the visible light ( $\lambda > 400$  nm) from the same Xe-lamp with an additional cutoff filter. The typical full spectrum of the Xe-lamp mainly locates in UV–vis range with wavelengths of 320–780 nm (Fig. S1) since the NIR irradiation of Xe-lamp was filtered with a reflector mirror. Generally, 15 mg of photocatalyst was dispersed into 150 mL of  $Na_2SO_3$  solution (1.0 mM) as hole sacrificial agent. Before the irradiation,  $N_2$  flow was bubbled into the suspension for 20 min to remove the dissolved  $O_2$ . The  $N_2$  flow could be imported into an Erlenmeyer flask with  $H_2SO_4$  solution to absorb the tail gas. During the photocatalytic experiment, the vessel was cooled to room temperature with a flow of cooling water and the experiment continued 2 h. The  $NH_3$  production amount was spectrophotometrically determined using indophenol blue method, and the

average  $\text{NH}_3$  production activity was calculated from the results of at least three parallel experiments. In addition, all photocatalysts have conducted blank test using Ar replacing  $\text{N}_2$ , which confirmed all color development reaction was stemmed from the  $\text{N}_2$  photofixation process but not the false appearance by the photocatalyst itself.

For the measurement of recycling stability, five consecutive  $\text{NH}_3$  production runs for total 20 h irradiation was performed under the same conditions. After one cycle for 4 h light irradiation, the photocatalyst was recovered by centrifugation and dried in vacuum oven, and then added in a new solution of sacrificial agent for the next run. Monochromatic light used in the measurement of apparent quantum efficiency (AQE) was acquired by inserting an appropriate band-pass filter ahead of the 300 W Xe-lamp to obtain the correct monochromatic light, and the value of light intensity was measured by using a SRC-1000-TC-QZ-N monocrystalline silicon cell (Oriel, USA). Each light intensity was calculated by the average intensity of nine point in the light spot which was chose uniformly at cross line. The  $\text{NH}_3$  yields were measured after 2 h photoreaction, and the AQE was calculated on the basis of the following equation [10]:

$$\text{AQE\%} = \frac{6 \times \text{number of evolved ammonia molecules}}{\text{number of incident photons}} \times 100\%$$

### 3. Results and discussion

#### 3.1. Crystal phase and valence state analyses

The X-ray diffraction (XRD) patterns of all Mn-doped products are very similar to that of the single one without Mn-doping (Fig. 1a), which delivers obvious diffraction peaks at  $2\theta = 23.3^\circ$  and  $47.7^\circ$  ascribable to the reflections of (010) and (020) planes of monoclinic  $\text{W}_{18}\text{O}_{49}$  (JCPDS No. 71-2450) [28], respectively. By using a commercial  $\text{SrTiO}_3$  as reference to mix with those Mn-doped  $\text{W}_{18}\text{O}_{49}$  products ( $x\text{Mn-W}_{18}\text{O}_{49}$ ), a gradual shift in the (010) peak of monoclinic  $\text{W}_{18}\text{O}_{49}$  along with the increase of Mn-doping level can be confirmed (Fig. 1b), while no shift is observed from the (100) (at  $2\theta = 22.6^\circ$ ) and (110) (at  $2\theta = 32.3^\circ$ ) peaks of cubic  $\text{SrTiO}_3$  (JCPDS No. 73-0661) [29]. This shift of (010) peak (up to  $0.22^\circ$  for 15% Mn- $\text{W}_{18}\text{O}_{49}$ ) toward higher  $2\theta$  angle implies that Mn species might dope into the crystal lattice of monoclinic  $\text{W}_{18}\text{O}_{49}$ .

The survey X-ray photoelectron spectra (XPS, Fig. 2a) indicate that those  $x\text{Mn-W}_{18}\text{O}_{49}$  products have obvious binding energy (BE) peaks of W4f and O1s in addition to weak one of Mn2p at  $\sim 640$  eV [30,31]. Along with the increase of Mn-doping level, the high resolution Mn2p spectra (Fig. 2b) present increasingly enhanced BE peaks at 641.8 eV ( $\text{Mn}^{2+} 2p_{3/2}$ ) and 653.9 eV ( $\text{Mn}^{2+} 2p_{1/2}$ ) of  $\text{Mn}^{2+}$ , and the satellite feature located in the range of 645–650 eV further confirms the Mn species is divalent (but not quadrivalent) [31–33]. The high resolution W4f spectrum (Fig. 2c) of the single  $\text{W}_{18}\text{O}_{49}$  can be de-convoluted into

two main BE peaks at 36.1 eV ( $\text{W}^{6+} 4f_{7/2}$ ) and 38.2 ( $\text{W}^{6+} 4f_{5/2}$ ) eV in addition to weak doublets at 34.7 and 36.9 eV, which can be assigned to the emission of  $\text{W}^{5+} 4f_{7/2}$  and  $\text{W}^{5+} 4f_{5/2}$  core level from  $\text{W}^{5+}$  [34–36]. It suggests the coexistence of  $\text{W}^{6+}/\text{W}^{5+}$  ions in the  $\text{W}_{18}\text{O}_{49}$  lattice. Moreover, the BE peak positons for those  $x\text{Mn-W}_{18}\text{O}_{49}$  products ( $0 < x \leq 7\%$ ) shift ca. 0.26 eV toward lower BE values, implying that  $\text{Mn}^{2+}$  doping can influence the chemical environments of  $\text{W}^{6+}/\text{W}^{5+}$  ions in the  $\text{W}_{18}\text{O}_{49}$  lattice. As shown in Fig. 2d, the O1s spectrum of the single  $\text{W}_{18}\text{O}_{49}$  can be deconvoluted into two symmetrical peaks at 530.9 and 531.9 eV, ascribable to the crystal lattice oxygen bonded with W atoms ( $\text{W-O-W}$ ) and the surface oxygen of  $-\text{OH}$  species ( $\text{W-OH}$ ) [37–39]. Similarly, the BE peaks at  $\sim 530.7$  and  $\sim 531.8$  eV for those  $x\text{Mn-W}_{18}\text{O}_{49}$  products also can be ascribed to the crystal lattice oxygen and the surface  $-\text{OH}$  group, respectively. In addition, a weak peak at 530.0 eV, ascribable to the oxygen atoms of Mn-O species, can be observed from those  $x\text{Mn-W}_{18}\text{O}_{49}$  products with  $x$  higher than 3% [32,33].

The above results demonstrate that the  $\text{Mn}^{2+}$  ions are doped into the  $\text{W}_{18}\text{O}_{49}$  lattice, and it can be conjectured that substitutional solid solution is formed in those  $x\text{Mn-W}_{18}\text{O}_{49}$  products according to the Hume-Rothery rule because the ionic radii of  $\text{W}^{6+}/\text{W}^{5+}$  (60/62 pm) in an octahedral coordination are close to that of  $\text{Mn}^{2+}$  (67 pm), and the electronegativity of W (1.7 Pau) is just slightly larger than that of Mn (1.5 Pau) [40,41]. The peak area ratio of surface  $-\text{OH}$  group and crystal lattice oxygen in O1s XPS spectra (Fig. 2d) increases from 0.41 ( $x = 0$ ), to 0.45 ( $x = 3\%$ ) and 0.49 ( $x = 7\%$ ), suggesting that more surface defects might be caused by  $\text{Mn}^{2+}$  replacing the  $\text{W}^{6+}/\text{W}^{5+}$  sites of  $\text{W}_{18}\text{O}_{49}$ . In addition, the electron paramagnetic resonance (EPR) spectra (Fig. S2) indicate that the single  $\text{W}_{18}\text{O}_{49}$  has no any paramagnetic response signal in the range of 300–400 mT, implying there is no obvious oxygen vacancies ( $\text{V}_\text{O}$ ) ( $g = 2.001$ ) existed in the single  $\text{W}_{18}\text{O}_{49}$  [9].

Usually, the stoichiometric  $\text{WO}_3$  lattice consists of  $\text{WO}_6$  octahedrons with corner connecting, while the structure of nonstoichiometric  $\text{W}_{18}\text{O}_{49}$  is distorted and restructured by sharing edges, which intrinsically forms low-valence W species and W–W metallic interaction in the lattice [14], and thus there is no obvious  $\text{V}_\text{O}$  signal. However, a six-line spectrum characteristic of isolated paramagnetic  $\text{Mn}^{2+}$ , arising from the hyperfine interaction with the  $^{55}\text{Mn}$  nuclear spin ( $I_{5/2}$ ) [42], is observed for all  $x\text{Mn-W}_{18}\text{O}_{49}$  products. Since  $\text{Mn}^{2+}$  ions instead of  $\text{W}^{6+}/\text{W}^{5+}$  sites in the  $\text{W}_{18}\text{O}_{49}$  lattice might lead to the formation of  $\text{V}_\text{O}$  sites for maintaining the charge balance in Mn- $\text{W}_{18}\text{O}_{49}$ , which would show an EPR signal at  $g = 2.001$  [9]. Nevertheless, the increase of  $\text{Mn}^{2+}$ -doping level causes a gradually enhanced EPR signals of Mn- $\text{W}_{18}\text{O}_{49}$ , but there is no any obvious EPR signal at  $g = 2.001$  for free electrons in  $\text{V}_\text{O}$  sites (Fig. S2), suggesting that electrons might prefer to be captured by  $\text{Mn}^{2+}$  ions rather than delocalized over the  $\text{W}_{18}\text{O}_{49}$  lattice [14], which would be a benefit to the photocatalytic process of  $\text{N}_2$  fixation. Furthermore, the increasing trends of EPR signal intensity (Fig. S2) and peak area ratios in O1s XPS spectrum (Fig. 2d)

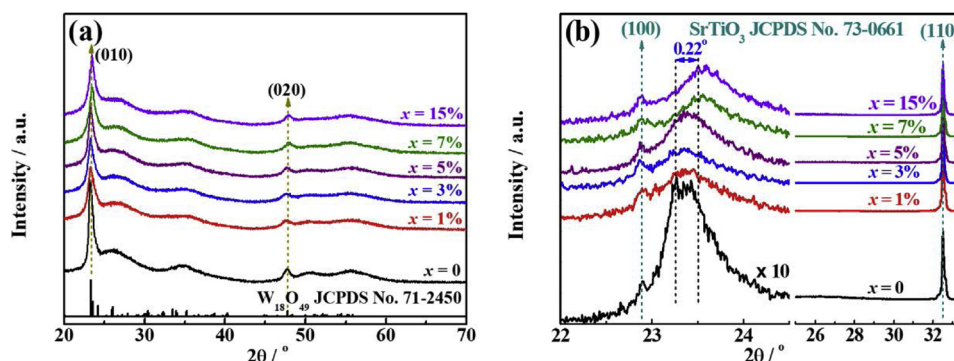

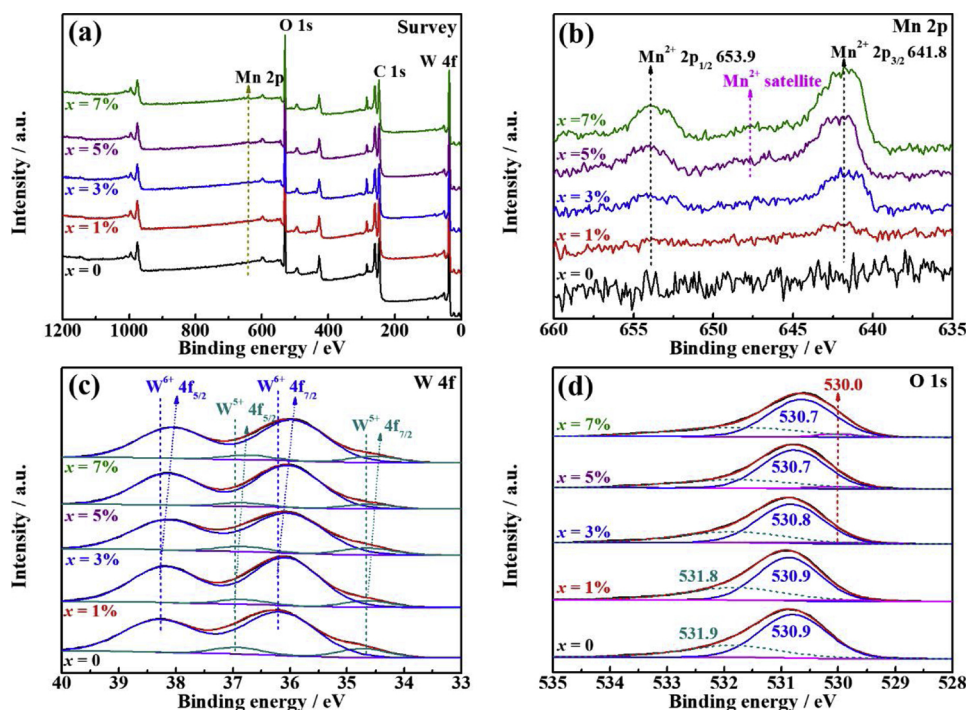

Fig. 1. (a) XRD patterns of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  ( $x = 0$ –15%) products derived from different Mn-doping levels. (b) XRD patterns at the lower angle regions ( $2\theta = 22^\circ$ – $25^\circ$  and  $25^\circ$ – $33.5^\circ$ ) of the mixtures containing  $x\text{Mn-W}_{18}\text{O}_{49}$  and  $\text{SrTiO}_3$ .

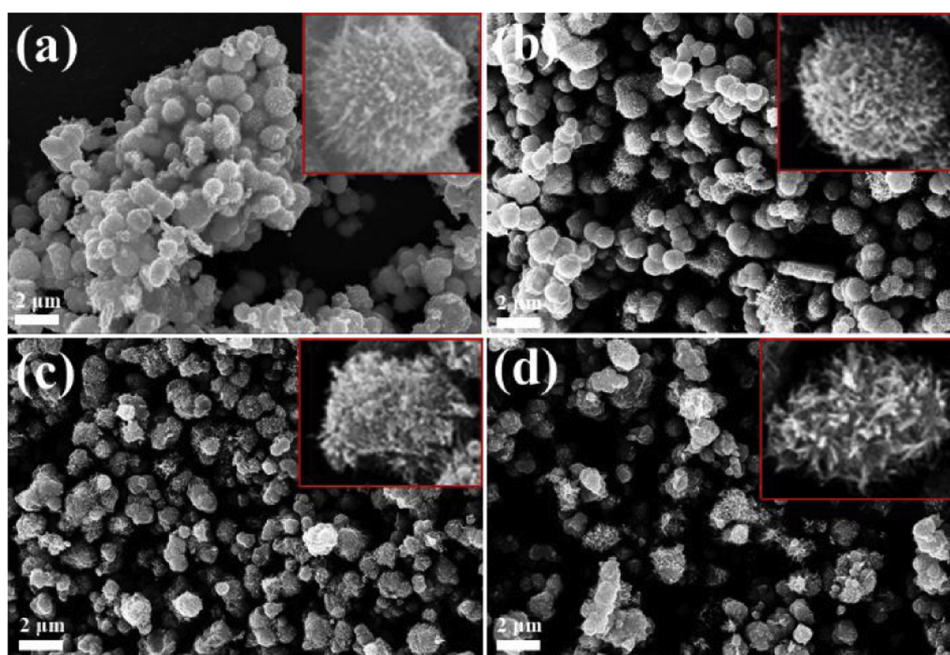

**Fig. 2.** The Survey and high resolution XPS spectra of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products with Mn-doping levels at 0–7%. (a) Survey, (b) Mn 2p (b), (c) W 4f and (d) O 1s.

demonstrate that the enhanced surface defects can be mainly ascribed to the surface  $\text{Mn}^{2+}$  doped sites when the Mn-doping level is enhanced from 0 to 7%, which can also enhance the reaction possibility for  $\text{N}_2$  photofixation as will be discussed below.

### 3.2. Microstructure and morphology analyses

FESEM image depicted in Fig. 3a exhibits that the single  $\text{W}_{18}\text{O}_{49}$  has sea-urchin-like microsphere morphology with sizes in the range of 1–2  $\mu\text{m}$ . Although the sea-urchin-like multilevelled structures can be maintained upon enhancing the Mn-doping levels (Fig. 3b–d), the

microsphere-like morphology is destructed gradually and changed into irregular ones. It implies that the  $\text{Mn}^{2+}$  doping would intervene the formation of microsphere-like structure. TEM image (Fig. 4a) shows that the sea-urchin-like microsphere is mainly constructed by regular nanorods with diameter in the range of 5–10 nm, and the HRTEM image (Fig. 4b) exhibits that the  $d$ -spacings of lattice fringes are ca. 0.377 nm and 0.370 nm, similar to the theoretical values of (010) and (103) facets of monoclinic  $\text{W}_{18}\text{O}_{49}$  [14], respectively. Besides, the Fast Fourier Transform (FFT) pattern displays obvious diffraction spots. These results infer that the single  $\text{W}_{18}\text{O}_{49}$  microsphere has high crystallinity, and its nanorods grow along the [010] orientation of monoclinic

**Fig. 3.** Typical FESEM images of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products with  $x = 0$  (a), 3% (b), 7% (c), 15% (d).

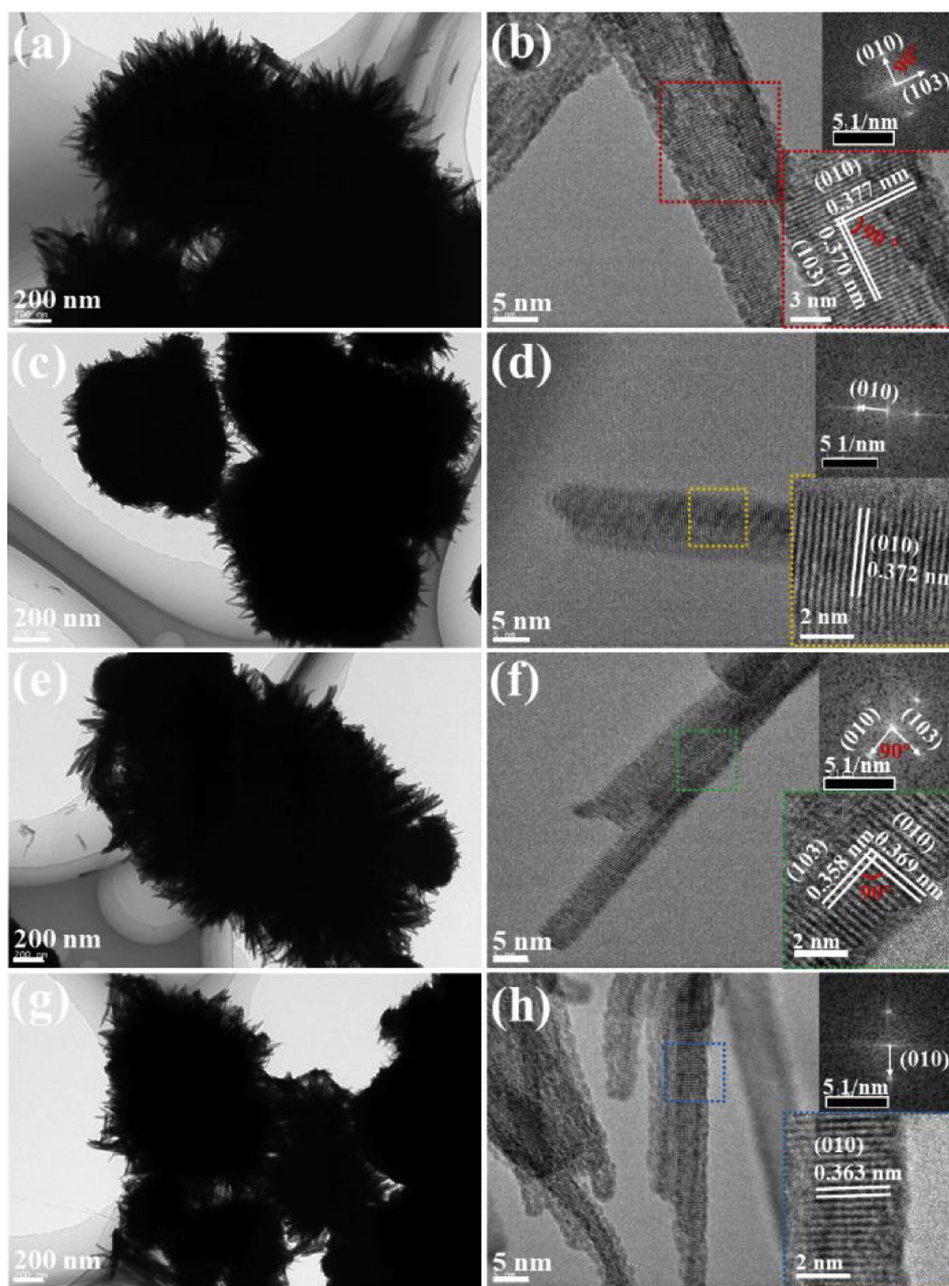

Fig. 4. Typical TEM (a, c, e, g) and HRTEM (b, d, f, h) images of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products with  $x = 0$  (b), 3% (d), 7% (f) and 15% (h).

$\text{W}_{18}\text{O}_{49}$ . Similarly, 3%  $\text{Mn-W}_{18}\text{O}_{49}$  still shows sea-urchin-like morphology constructed by nanorods (Fig. 4c), while the HRTEM image indicates that the  $d$ -spacing of lattice fringes for the nanorod is 0.372 nm (Fig. 4d), which is slightly lower than that of (010) plane of  $\text{W}_{18}\text{O}_{49}$ .

Although the microsphere-like morphology become more irregular along with the increase of Mn-doping level to 7% (Fig. 4e) and 15% (Fig. 4g), those nanorod-like structures are still remained. It can be found that the  $d$ -spacings (ca. 0.369 and 0.363 nm) of lattice fringes for 7%  $\text{Mn-W}_{18}\text{O}_{49}$  (Fig. 4f) and 15%  $\text{Mn-W}_{18}\text{O}_{49}$  (Fig. 4h) are lower than that (0.377 nm) of (010) plane for the single  $\text{W}_{18}\text{O}_{49}$ , implying that  $\text{Mn}^{2+}$  doping leads to the decrease in the  $d$ -spacings of  $\text{W}_{18}\text{O}_{49}$ . The above results indicate that  $\text{Mn}^{2+}$  doping would influence the formation of sea urchin-like microspheres with regular shape, but it does not affect the [010] growth orientation of  $\text{W}_{18}\text{O}_{49}$  nanorods, and therefore  $\text{Mn-W}_{18}\text{O}_{49}$  products still maintain sea-urchin-like multilevel structures constructed by nanorods.

Liquid  $\text{N}_2$  adsorption-desorption isotherms (Fig. S3a) indicate that all  $x\text{Mn-W}_{18}\text{O}_{49}$  products exhibit type II isotherms with H3 hysteresis loops, which is similar to that of the single  $\text{W}_{18}\text{O}_{49}$ . Along with the increase of Mn-doping level from 0 to 7%, the  $x\text{Mn-W}_{18}\text{O}_{49}$  products display a significant decreasing trend (from 162.1 to 103.9  $\text{m}^2 \text{g}^{-1}$ ) in the Brunauer-Emmett-Teller (BET) specific surface area ( $S_{\text{BET}}$ ). On the other hand, the Barret-Joyner-Halenda (BJH) pore size distribution plots (Fig. S3b) derived from the desorption branch reveal that the average pore diameter of  $x\text{Mn-W}_{18}\text{O}_{49}$  products exhibits a slight increase (6.6 nm to 8.2 nm) along with the decrease in the small pores with pore size in the range of 3–5 nm upon enhancing the Mn-doping level from 0 to 7%. These changes in micro/mesoporous structures can be due to the differences in the sea-urchin-like multilevel structure of those  $x\text{Mn-W}_{18}\text{O}_{49}$  products caused by the various  $\text{Mn}^{2+}$  doping levels, which will further influence the photoactivity as mentioned below.

### 3.3. Photocatalytic activity analyses

To investigate the photoactivities of  $x\text{Mn-W}_{18}\text{O}_{49}$  products, the photoreaction conditions for  $\text{N}_2$  fixation were optimized under full spectrum irradiation of Xe-lamp, and the quantitative determination of  $\text{NH}_3$  produced in the photoreaction suspension and the tail gas absorption solution was performed using chromogenic reaction with indophenol blue method [43]. A blank experiment with Ar flow instead of  $\text{N}_2$  demonstrated that no  $\text{NH}_3$  was produced from the irradiated photoreaction suspension. Since the raw sources are chlorides such as  $\text{WCl}_6$  and  $\text{MnCl}_2$ , those  $x\text{Mn-W}_{18}\text{O}_{49}$  products have no N-species remained during the material synthesis processes. This issue can be confirmed by the high resolution N1 s XPS spectra of those  $x\text{Mn-W}_{18}\text{O}_{49}$  products (Fig. S4), from which no obvious BE peak of N species can be observed. The above results suggest that the  $\text{NH}_3$  production is derived from the  $\text{N}_2$  photofixation reaction in the present photoreaction system.

Also, the effect of photocatalyst dosage on the  $\text{NH}_3$  production activity of the 3%Mn- $\text{W}_{18}\text{O}_{49}$  suspension (in 150 mL of 1.0 mM  $\text{Na}_2\text{SO}_3$  solution) under the full spectrum illumination of Xe-lamp. As seen from Fig. S5, 15 mg of photocatalyst exhibits the best  $\text{NH}_3$  production activity, and thus is an optimal photocatalyst dosage in the present photoreaction system. Under this photoreaction conditions, the single  $\text{W}_{18}\text{O}_{49}$  delivers a very limited  $\text{N}_2$  photofixation activity ( $29.3 \mu\text{mol g}^{-1} \text{h}^{-1}$ ) under Xe-lamp full spectrum illumination (Fig. 5a), while all  $x\text{Mn-W}_{18}\text{O}_{49}$  products deliver higher activities for  $\text{N}_2$  photoreduction toward  $\text{NH}_3$ , indicating that the  $\text{Mn}^{2+}$  doping could efficiently improve the  $\text{N}_2$  photofixation performance of  $\text{W}_{18}\text{O}_{49}$ . Along with the increase of Mn-doping level, the  $\text{N}_2$  photofixation activity of  $x\text{Mn-W}_{18}\text{O}_{49}$  products shows a firstly increasing trend and then a decreasing one, and 3% Mn- $\text{W}_{18}\text{O}_{49}$  achieves the highest  $\text{N}_2$  photofixation ability with an average  $\text{NH}_3$  production activity of  $97.9 \mu\text{mol g}^{-1} \text{h}^{-1}$  under the full spectrum illumination, which is 2.3 times higher than that of the single  $\text{W}_{18}\text{O}_{49}$ . Similarly, the  $\text{N}_2$  photofixation activity of  $x\text{Mn-W}_{18}\text{O}_{49}$  products shows a firstly increasing trend and then a decreasing one under visible light ( $\lambda > 400 \text{ nm}$ ) irradiation, and 3% Mn- $\text{W}_{18}\text{O}_{49}$  still delivers the highest activity of  $33.5 \mu\text{mol g}^{-1} \text{h}^{-1}$ , which was 3.6 times than that ( $7.3 \mu\text{mol g}^{-1} \text{h}^{-1}$ ) of the single  $\text{W}_{18}\text{O}_{49}$ .

The above results demonstrate that the optimal Mn-doping level in  $x\text{Mn-W}_{18}\text{O}_{49}$  is 3%, thus wavelength-dependent apparent quantum efficiencies (AQE) of 3% Mn- $\text{W}_{18}\text{O}_{49}$  were determined by detected the produced amount of  $\text{NH}_3$  under various monochromatic light irradiations. It was found that the AQE value's changing trend along with the illuminated wavelength matches with the intrinsic absorption capacity of  $\text{W}_{18}\text{O}_{49}$  with wavelength below 435 nm. Specifically, the AQE values at 350 and 435 nm are determined to be 0.14% and 0.023% (Fig. S6), respectively. In addition, 3% Mn- $\text{W}_{18}\text{O}_{49}$  has relatively stable  $\text{N}_2$  photofixation activity during the total 20 h photoreaction for 5 successive recycles (Fig. 5b). The recovered photocatalyst after the photoreaction shows a XRD pattern very similar to that of the original one (Fig. S7), in which the XRD peak positions and intensities of (010) and (020) are

basically identical even after the 3 recycles for photoreaction. Besides, the survey and W4f, O1 s, Mn2p high-resolution XPS spectra (Fig. S8a-d) of 3% Mn- $\text{W}_{18}\text{O}_{49}$  before and after the photoreaction show no obvious change. These results confirm the reusability and stability of the present Mn- $\text{W}_{18}\text{O}_{49}$ . It should be noticed that the BE peak intensity (at 401.7 eV) of N1 s XPS spectra (Fig. S8e) increases obviously, which is originated from the remnant  $\text{NH}_4^+$  after the photoreaction [44]. In addition, the pH value of the photoreaction suspension slightly decreases from 7.37 to 6.28 with prolonging the reaction time from 0 to 4 h (Fig. S9), this slightly decreased pH value also implied that some generated  $\text{NH}_4^+$  and  $\text{SO}_4^{2-}$  dissolved into the photoreaction suspension. Therefore, it can be convinced that the detected  $\text{NH}_3$  in the present photoreaction system is stemmed from the  $\text{N}_2$  photofixation reaction.

### 3.4. Photoelectrochemical and surface property analyses

To explore the effects of Mn doping on the  $\text{N}_2$  photofixation ability of  $x\text{Mn-W}_{18}\text{O}_{49}$  products, photoluminescence (PL) spectra and photocurrent response curves are tested and showed in Fig. 6. As can be seen from Fig. 6a, the PL peak intensity shows a firstly decreasing trend and then an increasing one along with the increase of Mn-doping level from 0 to 7%, and the 3% Mn- $\text{W}_{18}\text{O}_{49}$  displays the minimum PL peak intensity. It is consistent with the above photocatalytic performance shown in Fig. 5a, and demonstrating that 3% Mn- $\text{W}_{18}\text{O}_{49}$  has the most efficient charge separation among those  $x\text{Mn-W}_{18}\text{O}_{49}$  products [14]. Once the Mn-doping level is higher than 3%, the redundant doping  $\text{Mn}^{2+}$  ions might act as charge recombination centers of the photo-generated charge, and thus causes the PL peak intensity increase gradually. The photocurrent test results also present a similar conclusion. Among those products, the single  $\text{W}_{18}\text{O}_{49}$  shows the lowest photocurrent response (Fig. 6b), suggesting the single  $\text{W}_{18}\text{O}_{49}$  has the lowest defect concentration and the highest charge combination efficiency. With enhancing the  $\text{Mn}^{2+}$ -doping level, the photocurrent response values show an increasing trend firstly followed by a rapidly decreasing one, and 3% Mn- $\text{W}_{18}\text{O}_{49}$  delivers the largest photocurrent value among those products. The high photocurrent value is associated with the facilitated charge separation and migration [45], which might be the main reason that  $\text{Mn}^{2+}$  doping can improve the  $\text{N}_2$  photofixation efficiency.

The chemisorption and activation processes of  $\text{N}_2$  molecules are the essential problem in  $\text{N}_2$  fixation reactions because of the ultra-stable  $\text{N}\equiv\text{N}$  bond. To further explore this issue, the  $\text{N}_2$  temperature programmed desorption-mass spectrum ( $\text{N}_2$ -TPD-MS) experiments are conducted. In Fig. 7a, the  $\text{N}_2$ -TPD results indicate that the single  $\text{W}_{18}\text{O}_{49}$  has two desorbed peaks centered at ca. 130 and 400 °C, while 3% Mn- $\text{W}_{18}\text{O}_{49}$  displays three peaks centered at ca. 170, 393 and 535 °C. Obviously, the first peak position shifts to a higher temperature and a new weak peak is generated at ca. 535 °C. It implies that Mn-doping can change the adsorption property of  $\text{W}_{18}\text{O}_{49}$ . With the mass

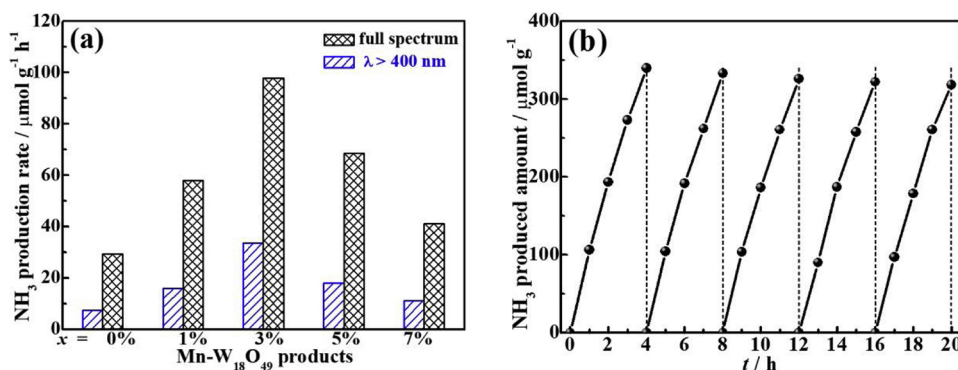

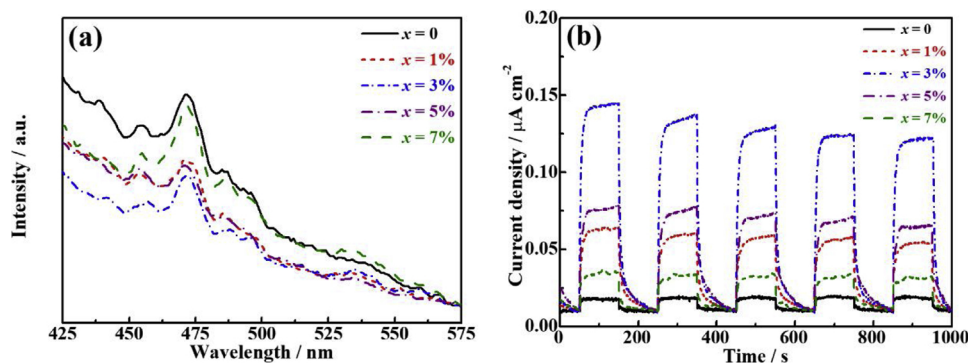

Fig. 5. (a) The average  $\text{NH}_3$  production activity of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products under full spectrum or visible light ( $\lambda > 400 \text{ nm}$ ) illumination for 2 h; (b) Cycling photocatalytic behavior towards  $\text{NH}_3$  production over 3% Mn- $\text{W}_{18}\text{O}_{49}$  under full spectrum illumination. Conditions: photocatalyst (15 mg) in  $\text{Na}_2\text{SO}_3$  (1.0 mM) solution (150 mL), 300 W Xe-lamp.

**Fig. 6.** (a) Photoluminescence (PL) spectra of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products with excitation wavelength of 325 nm. (b) photocurrent-time curves of the obtained  $x\text{Mn-W}_{18}\text{O}_{49}$  products under visible light ( $\lambda > 400$  nm) irradiation.

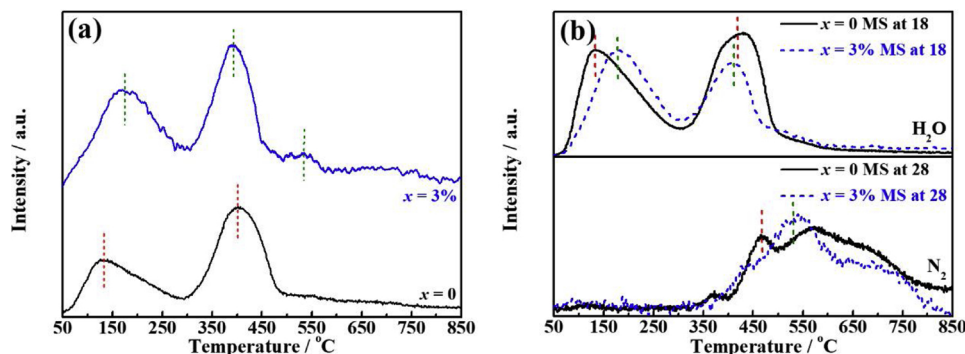

spectrometer as a detector of the  $\text{N}_2$ -TPD system, the MS spectra can be detected, and its results are shown in Fig. 7b, in which the MS peaks at 18 and 28 represent the  $\text{H}_2\text{O}$  and  $\text{N}_2$  molecules, respectively. As seen, the single  $\text{W}_{18}\text{O}_{49}$  shows two peaks at ca. 135 °C and 421 °C in the MS area of  $\text{H}_2\text{O}$  [46], while 3% Mn- $\text{W}_{18}\text{O}_{49}$  delivers a first peak with the position shifting toward higher temperature at ca. 180 °C. Similarly, 3% Mn- $\text{W}_{18}\text{O}_{49}$  also delivers a desorbed peak with the position shifting toward higher temperature at ca. 530 °C in the MS area of  $\text{N}_2$  compared to the single  $\text{W}_{18}\text{O}_{49}$ , which displays an obvious peak centered at ca. 470 °C followed a wide peak at ca. ~650 °C. Since the desorbed peak shift to higher temperature in TPD analyses represent the promotion of chemisorption ability [46,47], the above peak shifts in the MS areas of  $\text{H}_2\text{O}$  and  $\text{N}_2$  molecules imply that the  $\text{H}_2\text{O}$  and  $\text{N}_2$  chemisorption ability can be promoted by  $\text{Mn}^{2+}$  ions doped into the  $\text{W}_{18}\text{O}_{49}$  lattice, which then activate the H–O and  $\text{N}\equiv\text{N}$  bonds to be more accessible and easier to participate in the photoreaction for  $\text{N}_2$  photofixation to  $\text{NH}_3$  production.

### 3.5. Energy band structure and mechanism analyses

To further investigate the photocatalytic performance of the  $x\text{Mn-W}_{18}\text{O}_{49}$  products, the energy band structures are investigated. Fig. 8a present the UV–vis diffuse reflectance absorption spectra (DRS). As seen, the single  $\text{W}_{18}\text{O}_{49}$  show an onset absorption edge at ca. 513 nm, corresponding to the bandgap energy ( $E_g$ ) of ca. 2.4 eV, which was comparable to the value (2.6 eV [48]) reported before. With the enhancement of  $\text{Mn}^{2+}$ -doping level, the products display redshift obviously, and the  $E_g$  values of  $x\text{Mn-W}_{18}\text{O}_{49}$  decrease along with the increase of the  $x$  value. The onset absorption edge of  $x\text{Mn-W}_{18}\text{O}_{49}$  with  $x = 3\%$  and  $x = 7\%$  products were located at 549 nm and 604 nm, which were corresponding to the bandgap energy ( $E_g$ ) of 2.26 eV and 2.05 eV. The flat-band potentials ( $E_{fb}$ ) of the single  $\text{W}_{18}\text{O}_{49}$  (Fig. S10a) and 3% Mn- $\text{W}_{18}\text{O}_{49}$  (Fig. S10b) are determined from those Mott-

Schottky plots. Obviously, both the Mott-Schottky plots show positive slope, implying their n-type semiconducting property. The  $E_{fb}$  value of the single  $\text{W}_{18}\text{O}_{49}$  and 3% Mn- $\text{W}_{18}\text{O}_{49}$  were calculated by the intercepts with x-axis, the values can be determined to 0.36 V and 0.33 V vs. NHE [49], respectively. Because of the conduction band (CB) is 0.1 V higher than  $E_{fb}$  for n-type semiconductor, the  $E_{CB}$  level finally calculated to be 0.26 V and 0.23 V, respectively. The results are comparable to the value (0.21 eV [48]) reported before. It inferred that the valance band position ( $E_{VB}$ ) of the single  $\text{W}_{18}\text{O}_{49}$  and 3% Mn- $\text{W}_{18}\text{O}_{49}$  can deduced to be 2.52 V and 2.28 V according to the formula of  $E_g = E_{VB} - E_{CB}$ , respectively. Therefore, the  $E_{CB}$  and  $E_{VB}$  of the photocatalysts were calculated and a potential energy diagram of  $x\text{Mn-W}_{18}\text{O}_{49}$  products can be presented in Fig. 8b. As seen, the  $E_{CB}$  levels of both  $\text{W}_{18}\text{O}_{49}$  and 3% Mn- $\text{W}_{18}\text{O}_{49}$  are more negative than the potential of  $\text{N}_2$  converted to  $\text{NH}_4^+$  ( $\text{N}_2 + 8\text{H}^+ + 6\text{e}^- \rightarrow 2\text{NH}_4^+$ ,  $E^0 = 0.27$  V vs. NHE [7]), which confirmed that the reaction is accessible from the thermodynamics.

Based on the above experiment results and discussion, a possible  $\text{N}_2$  photofixation mechanism over the present Mn- $\text{W}_{18}\text{O}_{49}$  is proposed in Fig. 8b. Since there is large energy gap (10.82 eV) between the highest occupied molecular orbitals (HOMO) and lowest unoccupied molecular orbitals (LUMO) of  $\text{N}_2$  molecules, one or two-electron transfer reaction for  $\text{N}_2$  fixation is difficult, whereas a metal center can disrupt the  $\text{N}_2$  bonding system, and thus starts  $\text{N}_2$  activation toward further reactions, usually by enhancing its LUMO electron density due to more back donation of metal d-p electrons and by decreasing its HOMO electron density upon coordination [1]. As mentioned above, the  $\text{H}_2\text{O}$  and  $\text{N}_2$  chemisorption ability can be promoted by the surface  $\text{Mn}^{2+}$  ions of Mn- $\text{W}_{18}\text{O}_{49}$ , which then activate the H–O and  $\text{N}\equiv\text{N}$  bonds to be more accessible and easier to participate in the photoreaction for  $\text{N}_2$  photofixation to  $\text{NH}_3$  production. The sea-urchin-like Mn- $\text{W}_{18}\text{O}_{49}$  could absorb the UV and visible light and generate photogenerated electrons and holes, and then those photogenerated electrons would transfer to the adsorbed  $\text{N}_2$  molecules and form the activated  $\text{N}_2$  molecules.

**Fig. 7.** (a)  $\text{N}_2$ -TPD results of the  $x\text{Mn-W}_{18}\text{O}_{49}$  products ( $x = 0, 3\%$ ); (b)  $\text{N}_2$ -TPD-MS results with MS at 18 and 28 of the  $x\text{Mn-W}_{18}\text{O}_{49}$  products ( $x = 0, 3\%$ ).

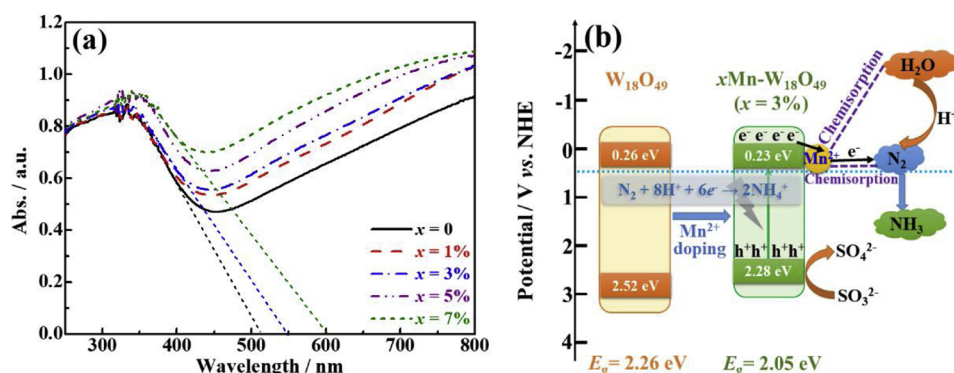

Fig. 8. (a) UV-vis diffuse reflectance absorption spectra (DRS) of the  $x\text{Mn-W}_{18}\text{O}_{49}$  products; (b) The possible mechanisms of  $\text{N}_2$  photofixation process over  $\text{Mn-W}_{18}\text{O}_{49}$ .

Meanwhile, the weakened H–O bonds after chemisorption  $\text{H}_2\text{O}$  molecules would generate more active  $\text{H}^+$  ions, which can react with those activated  $\text{N}_2$  molecules to produce  $\text{NH}_3$  through a proton coupling process. Those photogenerated holes will be consumed by the sacrificial reagent to avoid the recombination of photogenerated carriers. These results presented here are fundamentally important for understanding that  $\text{Mn}^{2+}$  doping sites could promote the photofixation  $\text{N}_2$  efficiency by acting as chemisorption and activation centers of both  $\text{N}_2$  and  $\text{H}_2\text{O}$  molecules, and therefore demonstrating a significant advance to more efficiently utilizing the transition metal element for UV/Vis-light-driven photofixation  $\text{N}_2$  through doping strategy.

#### 4. Conclusions

In summary, a series of  $\text{Mn}^{2+}$ -doped sea-urchin-like monoclinic  $\text{W}_{18}\text{O}_{49}$  microspheres ( $x\text{Mn-W}_{18}\text{O}_{49}$ ,  $0 \leq x \leq 7\%$ ), which are constructed by nanorods with [010] growth orientation and diameter of 5–10 nm, were synthesized via a facile solvothermal process. Although the  $\text{Mn}^{2+}$  ions instead of W sites in the monoclinic  $\text{W}_{18}\text{O}_{49}$  nanorods intervene the formation of microsphere-like morphology of  $\text{W}_{18}\text{O}_{49}$ , it does not change the growth orientation and shape of the nanorods in  $\text{Mn-W}_{18}\text{O}_{49}$  microspheres. Moreover, it is firstly found that  $\text{Mn}^{2+}$ -doped sites in  $\text{W}_{18}\text{O}_{49}$  can not only act as chemisorption and activation centers of  $\text{N}_2$  and  $\text{H}_2\text{O}$  molecules, but also facilitate the photoinduced charge separation and migration in  $\text{Mn-W}_{18}\text{O}_{49}$ , and thus cause an efficiently enhanced  $\text{N}_2$  photofixation ability toward  $\text{NH}_3$  production compared to the single  $\text{W}_{18}\text{O}_{49}$  microspheres under full spectrum or visible light irradiation. The present results provide new insights into the significance of transition metal element doping strategy for efficiently promoting the chemisorption and activation processes of ultra-stable  $\text{N}_2$  molecules, thus paving new way to the design and synthesis of high-performance, easily available materials for  $\text{N}_2$  photofixation under the mild condition.
